8.3 The Process of
Photosynthesis

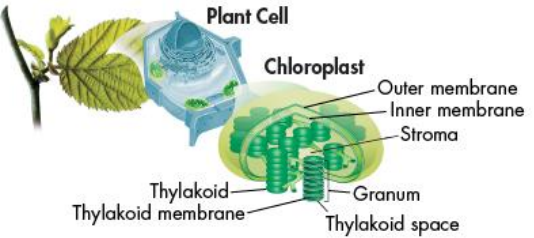

Miller & Levine
Biology

Lesson Overview The Process of Photosynthesis

THINK ABOUT IT

- Why do chloroplasts contain so many membranes?
- When most pigments absorb light, they eventually lose most of that energy as heat. Chloroplasts avoid such losses. Membranes are the key to capturing light energy in the form of high-energy electrons.

Lesson Overview The Process of Photosynthesis

Plant Cell

Chloroplast

- Outer membrane
- Inner membrane

- Thylakoid
- Thylakoid membrane
- Granum
- Thylakoid space

Lesson Overview The Process of Photosynthesis

The Light-Dependent Reactions: Generating ATP and NADPH

What happens during the light-dependent reactions?

Lesson Overview The Process of Photosynthesis

The Light-Dependent Reactions: Generating ATP and NADPH

The light-dependent reactions use energy from sunlight to produce oxygen and convert ADP and NADP⁺ into the energy carriers ATP and NADPH.

Lesson Overview The Process of Photosynthesis

The Light-Dependent Reactions: Generating ATP and NADPH

The light-dependent reactions encompass the steps of photosynthesis that directly involve sunlight.

The light-dependent reactions occur in the thylakoids of chloroplasts.

The diagram illustrates the two stages of photosynthesis within a chloroplast. On the left, the light-dependent reactions occur in the thylakoid membranes, where light energy and water (H₂O) are used to produce oxygen (O₂) and energy carriers ATP and NADPH. On the right, the light-independent reactions (Calvin cycle) occur in the stroma, where carbon dioxide (CO₂) is fixed into sugars using the energy from ATP and NADPH.

Lesson Overview The Process of Photosynthesis

The Light-Dependent Reactions: Generating ATP and NADPH

Lesson Overview The Process of Photosynthesis

The Light-Dependent Reactions: Generating ATP and NADPH

Thylakoids contain clusters of chlorophyll and proteins known as **photosystems**.

Photosystems absorb sunlight and generate **high-energy electrons** that are then passed to a series of electron carriers embedded in the thylakoid membrane.

Lesson Overview The Process of Photosynthesis

Photosystem II

Light energy is absorbed by electrons in the pigments within **photosystem II**, increasing the electrons' energy level.

The high-energy electrons are passed to the **electron transport chain**, a series of electron carriers that shuttle high-energy electrons during ATP-generating reactions.

Lesson Overview The Process of Photosynthesis

Photosystem II

- The thylakoid membrane provides new electrons to chlorophyll from water molecules.
- Enzymes of the inner surface of the thylakoid break up water molecules into 2 electrons, 2 H⁺ ions, and 1 oxygen atom.

Lesson Overview The Process of Photosynthesis

Photosystem II

- The 2 electrons replace the high-energy electrons that have been lost to the electron transport chain.
- Oxygen is released into the air. This reaction is the source of nearly all of the oxygen in Earth's atmosphere.
- The H⁺ ions are released inside the thylakoid.

Lesson Overview The Process of Photosynthesis

Electron Transport Chain

Energy from the electrons is used by proteins in the electron transport chain to pump H⁺ ions from the stroma into the thylakoid space.

Lesson Overview The Process of Photosynthesis

Electron Transport Chain

At the end of the electron transport chain, the electrons are passed to photosystem I.

Lesson Overview The Process of Photosynthesis

The End Result of Photosystem II

The splitting of water molecules provide electrons for transport and produce oxygen gas

The buildup of H⁺ ions makes the stroma negatively charged relative to the space within the thylakoids.

Lesson Overview The Process of Photosynthesis

Photosystem I

Because some energy has been used to pump H⁺ ions across the thylakoid membrane, electrons do not contain as much energy as they used to when they reach photosystem I.

Pigments in photosystem I use energy from light to reenergize the electrons.

Lesson Overview The Process of Photosynthesis

Photosystem I

At the end of a short second electron transport chain, NADP⁺ molecules in the stroma pick up the high-energy electrons and H⁺ ions at the outer surface of the thylakoid membrane to become NADPH.

The diagram illustrates the process at Photosystem I. Light energy is absorbed by the thylakoid membrane, exciting electrons. These electrons are passed through electron carriers to NADP⁺ in the stroma, which is reduced to NADPH. Simultaneously, protons (H⁺) are pumped from the stroma into the thylakoid space. Labels include: CYTOPLASM, Light, Thylakoid membrane, Photosystem I, Electron carriers, ATP synthase, STROMA, and THYLAKOID SPACE. Chemical equations shown are: $2\text{H}^+ + 2\text{NADP}^+ + 4e^- \rightarrow 2\text{NADPH}$ and $2\text{H}_2\text{O} \rightarrow 4\text{H}^+ + \text{O}_2$.

Lesson Overview The Process of Photosynthesis

Hydrogen Ion Movement and ATP Formation

H⁺ ions accumulate within the thylakoid space from the splitting of water molecules that are pumped in from the stroma.

The buildup of H⁺ ions makes the stroma negatively charged relative to the space within the thylakoids.

This diagram highlights the proton gradient. Light energy drives the electron transport chain, and protons (H⁺) are pumped from the stroma into the thylakoid space. The resulting gradient is used by ATP synthase to produce ATP. Labels include: CYTOPLASM, Light, Thylakoid membrane, Photosystem I, Electron carriers, ATP synthase, STROMA, and THYLAKOID SPACE. Chemical equations shown are: $2\text{H}^+ + 2\text{NADP}^+ + 4e^- \rightarrow 2\text{NADPH}$ and $2\text{H}_2\text{O} \rightarrow 4\text{H}^+ + \text{O}_2$.

Lesson Overview The Process of Photosynthesis

Hydrogen Ion Movement and ATP Formation

This gradient, the difference in both charge and H⁺ ion concentration across the membrane, provides the energy to make ATP.

The diagram shows ATP synthase embedded in the thylakoid membrane. Protons (H⁺) flow from the thylakoid space back into the stroma through the enzyme, driving the synthesis of ATP from ADP and inorganic phosphate. Labels include: CYTOPLASM, Light, Thylakoid membrane, Photosystem I, Electron carriers, ATP synthase, STROMA, and THYLAKOID SPACE. Chemical equations shown are: $2\text{H}^+ + 2\text{NADP}^+ + 4e^- \rightarrow 2\text{NADPH}$ and $2\text{H}_2\text{O} \rightarrow 4\text{H}^+ + \text{O}_2$.

Lesson Overview The Process of Photosynthesis

Hydrogen Ion Movement and ATP Formation

H⁺ ions cannot directly cross the thylakoid membrane. However, the thylakoid membrane contains a protein called **ATP synthase** that spans the membrane and allows H⁺ ions to pass through it.

Lesson Overview The Process of Photosynthesis

Hydrogen Ion Movement and ATP Formation

Powered by the gradient, H⁺ ions pass through ATP synthase and force it to rotate.

As it rotates, ATP synthase binds ADP and a phosphate group together to produce ATP.

Lesson Overview The Process of Photosynthesis

Hydrogen Ion Movement and ATP Formation

This process, called **chemiosmosis**, enables light-dependent electron transport to produce not only **NADPH** (at the end of the electron transport chain), but **ATP** as well.

Lesson Overview The Process of Photosynthesis

Summary of Light-Dependent Reactions

The light-dependent reactions produce oxygen gas and convert ADP and NADP⁺ into the energy carriers ATP and NADPH.

Light-dependent reactions take place on and inside the thylakoid space of the chloroplasts

ATP and NADPH provide the energy needed to build high-energy sugars from low-energy carbon dioxide.

Lesson Overview The Process of Photosynthesis

The Light-Independent Reactions: Producing Sugars

What happens during the light-independent reactions?

Lesson Overview The Process of Photosynthesis

The Light-Independent Reactions: Producing Sugars

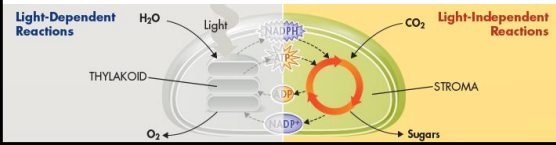

What happens during the light-independent reactions?

During the light-independent reactions, **ATP** and **NADPH** from the light dependent reactions are used to produce high-energy sugars.

Lesson Overview The Process of Photosynthesis

The Light-Independent Reactions: Producing Sugars

During the light-independent reactions, commonly referred to as the **Calvin cycle**, plants use the energy that **ATP** and **NADPH** contains to build stable high-energy **carbohydrate** compounds that can be stored for a long time.

Lesson Overview The Process of Photosynthesis

Carbon Dioxide Enters the Cycle

- Carbon dioxide molecules enter the Calvin cycle from the atmosphere.
- An enzyme in the stroma of the chloroplast combines carbon dioxide molecules with 5-carbon compounds that are already present in the organelle, producing 3-carbon compounds that continue into the cycle.

Lesson Overview The Process of Photosynthesis

Carbon Dioxide Enters the Cycle

For every six carbon dioxide molecules that enter the cycle, a total of twelve 3-carbon compounds are produced.

Lesson Overview The Process of Photosynthesis

Sugar Production

At midcycle, two of the twelve 3-carbon molecules are removed from the cycle.

These molecules become the building blocks that the plant cell uses to produce sugars, lipids, amino acids, and other compounds.

Lesson Overview The Process of Photosynthesis

Sugar Production

The remaining **ten** 3-carbon molecules are converted back into **six** 5-carbon molecules that combine with six new carbon dioxide molecules to begin the next cycle.

Lesson Overview The Process of Photosynthesis

Summary of the Calvin Cycle

The **Calvin cycle** uses **six** molecules of carbon dioxide to produce a **single** 6-carbon sugar molecule.

$C_6H_{12}O_6$

Lesson Overview The Process of Photosynthesis

Summary of the Calvin Cycle

The energy for the reactions is supplied by compounds produced in the **light-dependent** reactions.

This means that photosynthesis can **NOT** occur without sunlight.

Lesson Overview The Process of Photosynthesis

The End Results

The diagram illustrates the two stages of photosynthesis within a chloroplast. On the left, the light-dependent reactions occur in the thylakoid membranes, where light energy and water (H₂O) are used to produce oxygen (O₂) and the energy carrier NADPH. On the right, the light-independent reactions (the Calvin cycle) occur in the stroma, where carbon dioxide (CO₂) is fixed into sugars using the energy from NADPH and ATP.

Lesson Overview The Process of Photosynthesis

Summary of the Calvin Cycle

The plant uses the sugars produced by the Calvin cycle to meet its energy needs and to build macromolecules needed for growth and development.

When other organisms eat plants, they can use the energy and raw materials stored in these compounds.

The diagram shows the Calvin cycle in the stroma. It starts with 6 molecules of CO₂ entering from the cytoplasm. These combine with 12 molecules of a 3-carbon compound (from light-dependent reactions) to form 12 molecules of a 6-carbon intermediate. This intermediate is then used to produce 6 molecules of a 6-carbon sugar (glucose) and 2 molecules of a 3-carbon compound, which are used for other cellular processes. The cycle is powered by ATP and NADPH from the light-dependent reactions.

Lesson Overview The Process of Photosynthesis

The End Results

The two sets of photosynthetic reactions work together—the light-dependent reactions trap the energy of sunlight in chemical form, and the light-independent reactions use that chemical energy to produce stable, high-energy sugars from carbon dioxide and water.

In the process, animals, including humans, get food and an atmosphere filled with oxygen.

Lesson Overview The Process of Photosynthesis

The End Results

The diagram illustrates the two stages of photosynthesis within a chloroplast. On the left, the thylakoid membranes are shown as a stack of green discs. Light energy is represented by a yellow arrow hitting these membranes. Water (H₂O) enters from the left and is split into oxygen (O₂) and electrons. Electrons are transferred to NADP⁺, which becomes NADPH. On the right, the stroma is shown as a fluid-filled space. Carbon dioxide (CO₂) enters from the right. The energy from NADPH and ATP (produced in the thylakoids) is used to convert CO₂ into sugars. ATP is then converted back to ADP, which is recycled back to ATP in the thylakoids.

Lesson Overview The Process of Photosynthesis

Factors Affecting Photosynthesis

What factors affect photosynthesis?

Among the most important factors that affect photosynthesis are **temperature, light intensity, and the availability of water.**

Lesson Overview The Process of Photosynthesis

Photosynthesis Under Extreme Conditions

In order to conserve water, most plants under bright, hot conditions close the small openings in their leaves that normally admit carbon dioxide.

This causes carbon dioxide within the leaves to fall to very low levels, slowing down or even stopping photosynthesis.

C4 and CAM plants have biochemical adaptations that minimize water loss while still allowing photosynthesis to take place in intense sunlight.

C4 Photosynthesis: (**NOT** cyclotrimethylene trinitramine)

C4 plants have a specialized chemical pathway that allows them to capture even very low levels of carbon dioxide and pass it to the Calvin cycle.

C4 plants have a competitive advantage over plants possessing the more common C3 carbon fixation.

C4 Plants are more successful under conditions of drought, high temperatures, and nitrogen or CO₂ limitation.

C4 Photosynthesis

The name “C4 plant” comes from the fact that the first compound formed in this pathway contains 4 carbon atoms.

The C4 pathway requires extra energy in the form of ATP to function.

C4 organisms include crop plants like corn, sugar cane, and sorghum.

Lesson Overview

The Process of Photosynthesis

CAM Plants

Members of the Crassulaceae family, such as cacti and succulents, incorporate carbon dioxide into organic acids during photosynthesis in a process called Crassulacean Acid Metabolism (CAM).

Lesson Overview The Process of Photosynthesis

CAM Plants

CAM plants are adapted to dry climates and use a different strategy to use carbon dioxide while minimizing water loss.

CAM plants include pineapple plants, many desert cacti, and "ice plants".
